## Agent Tesla: Evading EDR by Removing API Hooks

by Ratnesh Pandey on August 23, 2019

*Written by Toby Gray and Ratnesh Pandey.*

Endpoint detection and response (EDR) tools rely on operating system events to detect malicious activity that is generated when malware is run. These events are later correlated and analysed to detect anomalous and

suspicious behaviour. One of the sources for such events are application program interface (API) hooks that help EDR solutions to trace interesting API calls. We recently came across a phishing campaign delivering the Agent Tesla password-stealing Trojan. While analysing the forensic data captured by [Bromium Secure Platform](#), we noticed memory tampering events in the address space of ntdll.dll, the dynamic-link library (DLL) that exports the Windows Native API. The payload was isolated by Bromium Secure Platform and captured the malware.

The Agent Tesla downloader arrived as a .xls file which drops and executes the primary payload. In this blog post we cover the unhooking of APIs by the dropper to evade detection by tools such as EDR that rely on hooking. In a subsequent blog post, we provide an in-depth analysis of the campaign.

## System Calls

A system call is a function in the kernel of an operating system that services requests from users and provides a barrier so that underlying high-privilege resources cannot be directly accessed by the user. On Windows systems, the ntdll.dll library contains user mode system calls. Information about these system calls are stored in an array of function pointers and the System Service Descriptor Table (SSDT).

Figure 1 – The SERVICE\_TABLE\_DESCRIPTOR data structure contains a pointer to array of system calls.

The “Base” points to the function pointer array and the system call number is an index into this array. These functions are used to request the kernel to perform some action, such as allocating virtual memory in the case of [NtAllocateVirtualMemory](#). For the rest of this discussion we’ll focus on NtProtectVirtualMemory, which is an undocumented system call that’s used to change the permissions of memory.

## 32-bit code on 64-bit Windows

When a 32-bit program is run on a 64-bit Windows machine, it runs under a system known as Windows on Windows 64 (or WoW64 for short). Because the kernel is running in 64-bit mode, system calls from 32-bit programs all go via a wrapper function, Wow64SystemServiceCall, which is at a known location in memory. This means that ntdll.dll, which contains many system call functions, has a very repetitive structure:

Figure 2 – Disassembly of NtProtectVirtualMemory.

The four lines of the disassembly code of NtProtectVirtualMemory are broken down as:

- Load the system call number 0x50 into the eax register

- Put the location of Wow64Transition (0x77BC2430 in the above screenshot) into the edx register
- Call the function at edx
- Return from this function

The next system call function, ZwQuerySection, is immediately after this one and follows the same structure, the only difference being loading 0x51 as the system call number rather than 0x50.

## Hooking APIs

Security products use API hooking to intercept and record system API calls from software. One way of accomplishing this is to modify the in-memory code for the API that is to be hooked.

When hooked, the first instruction is replaced by an instruction that jumps to the trampoline code generated by the hooking software.

Figure 3 – Original function of NtProtectVirtualMemory is overwritten with 5-byte jmp instruction.

In figure 3, the first instruction of NtProtectVirtualMemory no longer loads 0x50 into eax; instead it redirects execution of the code (or jumps) to the address 0x004F0012. The hooking code will have generated code at that address which:

- Performs the action that hooking was added for, this could be a combination of:
  - Recording the API call to monitor activity
  - Modifying the API call to prevent certain actions
  - Blocking the API to stop malicious activity
- Performs the replaced instruction (mov eax, 50 in this case, so setting the eax register to 0x50)
- Jumps execution back to the next instruction in the original function (0x77BAE215 in this case)

Weaknesses in API Security

As the original function then continues execution as usual, neither the code calling the API nor the system kernel are aware that the function call has been intercepted.

Modern malware typically relies on polymorphism and obfuscation techniques to evade static detection by signature-based detection technologies such as anti-virus. EDR tools work differently by monitoring system activity and flagging suspicious events if there is a deviation from normal application behaviour or if there is a match against known malicious patterns. Most of these events are generated by hooking APIs.

Some security solutions also use API hooks to block malicious processes if a suspicious event is triggered.

When analysing this malicious sample we noticed some unique code that was modifying the memory-mapped ntdll.dll before launching its payload, Agent Tesla (bin.exe). The malware allocates the shellcode and then performs the following actions:

- Call NtProtectVirtualMemory in ntdll.dll's address space to change its memory permissions of the region to PAGE\_EXECUTE\_READWRITE
- Removes the API hooks from ntdll.dll as described below
- Call NtProtectVirtualMemory to reset the page permissions of the region back to PAGE\_EXECUTE\_READ
- After removing the hooks, it executes the main payload via the ShellExecuteW API

Figure 4 – Shellcode that removes the API hooks.

The malicious code loads the address of Wow64SystemServiceCall into the edx register before scanning through the memory of ntdll.dll a byte at a time. In the above code, the instruction at 0x004A0A50 is incrementing the ebx register, which contains the location of the next part of ntdll.dll to examine.

The first check at 0x004A0A51 is performing a check unrelated to unhooking the type of hook described previously, so skip over that comparison and jump to 0x004A0A6B. The check at 0x004A0A6B is for the value of Wow64Transition and if it's found then the instructions starting at 0x004A0A6F are performed. In sequence these are:

- Write the value in eax (which is a counter for the system call number, so 0x50 in the case of NtProtectVirtualMemory) out to 5 bytes before the location of the value of Wow64Transition.
- Write the byte 0xB8 out to 6 bytes before the location of the value of Wow64Transition.
- Increment the value in eax, moving the system call number onto the next value

The result of writing out the 5 bytes (4 for eax and one for 0xB8) is to replace any hooking instruction (such as jmp 0x004F0012 in the previous example) with the original instruction that was there (which is mov eax, 50 in the previous example).

The end result is that the malicious code can now call system APIs, safe in the knowledge that its requests won't be monitored or blocked by any hooks.

This unhooking isn't an issue for Bromium Secure Platform as the malicious activity will still all be contained inside a micro-virtual machine (uVM) where hardware-backed isolation is used for protection.
